Abstract

The local available-enthalpy cycle proposed in Part I of this paper is applied to document energetics of three numerical simulations, representing life cycles of idealized baroclinic waves. An improved temporal numerical scheme defined in Part I is used in this study, together with the Arpege-IFS model using a T42 triangular truncation. A 45 °N and 200 hPa dry unstable jet is constructed with the most unstable mode at zonal wave number 8. Energetic impacts of both horizontal and vertical diffusion schemes are determined separately.

The role of ageostrophic winds within the Ekman layer is investigated, leading to an explanation for large observed values for the dissipation terms and to a new formulation of the potential-energy conversions. The magnitudes of these new conversion terms are compared with those of the usual barotropic and baroclinic conversions. A new version for the available-enthalpy cycle is proposed. It is suitable for open systems and it includes explicitly the potential-energy component as a transitional reservoir. Finally, some results from Intensive Observing Period 15 of the Fronts and Atlantic Storm-Track EXperiment (FASTEX) are compared with those from the idealized diabatic experiment.

1 Introduction.

In the first part of this paper (Marquet, 2003, hereafter referred to as Part I), a local and exact available-enthalpy cycle has been proposed. It is designed to clear up the difficulties encountered with previous limited-area applications and, on the global stage, it must lead to the generally accepted results, including conventional baroclinic and barotropic instabilities.

The main local results of Part I are briefly recalled in section 2 and other global results are derived. Adiabatic and diabatic simulations of a life cycle of idealized baroclinic waves are described in section 3. The properties of the new cycle are examined in section 4, based on global and local applications. The temporal scheme defined in Part I is used with a time interval of 3 hours. It is explained how Ekman dissipation and ageostrophic circulations can account for observed large values for dissipation and conversion terms with potential energy in the boundary layer. A new version for the available-enthalpy cycle, suitable for open systems, is proposed in section 5. It includes the potential-energy component as a transitional reservoir in the Lorenz cycle, located between available-enthalpy and kinetic-energy reservoirs. Some results from Intensive Observing Period (IOP15) of Fronts and Atlantic Storm-Track EXperiment (FASTEX) are compared with the diabatic idealized experiment in section 6, with final conclusions presented in section 7.

2 The limited area available enthalpy cycle.

It is explained in Part I that the budget equations for the available enthalpy are derived by computing the time derivation of the six components a_S , a_Z , a_E , k_S , k_Z and k_E (all symbols are defined in Appendix-A of Part I). As a result, the available-enthalpy cycle is given by (36) and by Fig. 5(b) in Part I.

The global version of (36) in Part I is given by (1)-(3). These equations for A_h , K and the total energy $TOT = A_h + K$ are obtained when the whole limited-area domain is considered and by integration from the top pressure p_t to the bottom value p_b .

$$\partial_t(A_h) = -B(A_h) - (C_S + C_Z + C_E) - B(A_p) + G, \quad (1)$$

$$\partial_t(K) = -B(K) + (C_S + C_Z + C_E) - B(\phi) - D, \quad (2)$$

$$\partial_t(TOT) = -[B(A_h) + B(K) + B(A_p) + B(\phi)] + G - D. \quad (3)$$

Boundary terms $B(A_h)$, $B(K)$, $B(A_p)$ and $B(\phi)$ all vanish for $z_b = 0$, $p_b = \text{constant}$, $p_t = 0$ and for a domain surrounding the whole Earth. These assumptions have been retained in the study of Lorenz (1955, hereafter L55) where the total energy is a constant for a pure adiabatic model if $G - D$ is equal to zero. However G and D are generally non-zero in numerical simulations because the total energy is not rigorously conserved. Indeed, horizontal spectral schemes are applied on a truncated spectral space, leading to approximations and errors. There are other errors due to time or vertical differencing schemes and interpolation methods. The validation of adiabatic and frictionless versions of the cycle (36) of Part I will be obtained by taking $G = D$ and if the residuals are both small in comparison with the physical tendencies generated by diabatic processes (i.e. $|G| < \epsilon$ and $|D| < \epsilon$).

3 Numerical simulations of baroclinic waves.

The concepts of local energetics will be illustrated by a study of available-enthalpy diagnostics for life-cycle experiments of idealized baroclinic waves. Energy computations every 3 h will be undertaken for three different numerical simulations with the same basic state used as a common starting point. This basic state is obtained by suppressing orography and by setting the humidity to a very small value (but non zero to avoid numerical problems in the physics package). The constant surface pressure is equal to 1013.25 hPa. The French Arpege¹ numerical model (Courtier *et al.*, 1991) is used with a triangular truncation at total wave number 42, with 31 irregularly spaced hybrid levels and an Eulerian semi-implicit leapfrog time step of 900 s.

The first adiabatic experiment (EXP-A) is subject only to weak numerical dissipation or generation created by the Asselin filter, truncation errors or approximate time or vertical differencing schemes. There are no explicit horizontal and vertical diffusion schemes. This adiabatic and frictionless simulation will serve as a validation for the new energetic analysis, leading to a quasi-conservative total energy and giving expected small values for dissipation and generation terms expressed as residuals (including the numerical errors). Nevertheless, the last days of this simulation are somewhat unrealistic due to an accumulation of small-scale noisy features associated with high total wavenumber. As a consequence only the growing stage will be considered for (EXP-A), namely for the first 10 days.

The second experiment (EXP-H) is also adiabatic and frictionless but with an additional ∇^6 horizontal diffusion scheme to avoid the accumulation of energy in the high wave number. The

¹The name ‘‘Arpege’’ means ‘‘Action de Recherche Petite Echelle et Grande Echelle’’ in French (this means ‘‘Large-scale and Small-scale Research Program’’). It is the French counterpart of the ECMWF-IFS model. It share the same dynamic core since 1988, but with a specific physics package. Arpege is often used with a variable grid mesh, based on the stretched and titled pole grid option.

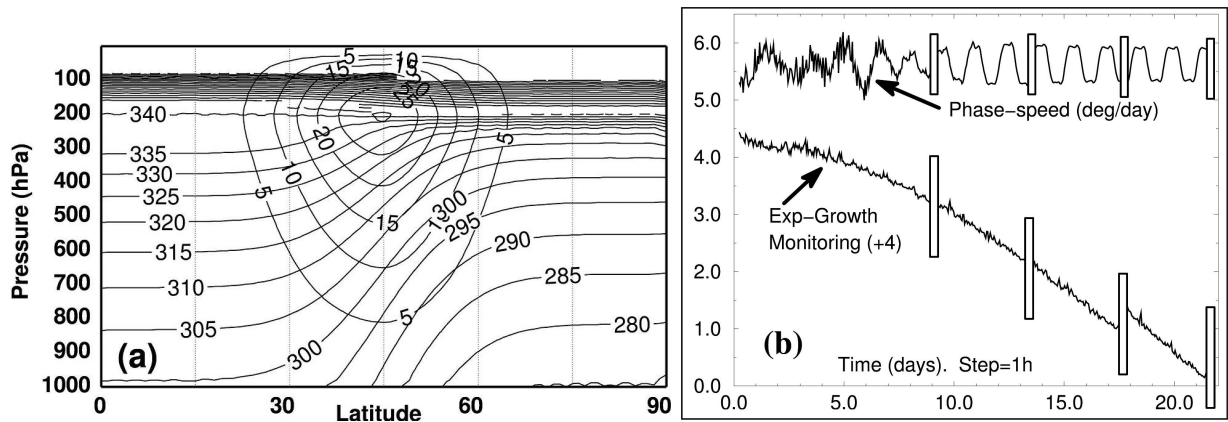

Figure 1: (a): latitude-height section for the basic state showing potential temperature with an interval of 5 K and zonal velocity interval of 5 m s⁻¹. (b): the diagnostics of Simmons and Hoskins (1976) for the 22 days simulation of the selection of the most unstable mode at zonal wave number 8. The phase speed is depicted in the upper part in degrees/day and the relative change in growth rate from one hour to the next is depicted on the lower part (going from 0 to -4, with +4 unit added for ease of plotting). There are four interruptions at about 9.2, 13.5, 17.7 and 21.5 days, located at times when the perturbation amplitude of the mode is reduced when it became too large (see Thorncroft and Hoskins, 1990). The improved definition of (A.2) in the Appendix has no influence on the oscillations observed for the phase speed after day 5 of the simulation. An explanation is still to be discovered.

stage of decay of the baroclinic wave is more realistic than for EXP-A. The e-folding time of the horizontal diffusion scheme is 12 h for the vorticity and temperature, 4 h for the divergence.

Table 1: The mixing length L for EXP-HV. Values are given for height 0 to 4000 m. There is a “ $L = 0.4z$ ” law close to the surface, with a maximum values $L \approx 45$ m at $z = 700$ m, with reduction towards the asymptotic value $L = 9$ m in the higher troposphere and above.

Height	0	5	50	100	250	500	750	1000	1500	2000	3000	4000
L-mix	0	2	15	24	37	44	45	43	38	32	24	19

The third diabatic experiment (EXP-HV) includes the same ∇^6 horizontal diffusion as for EXP-H, but with a vertical diffusion scheme added. As a result, ageostrophic circulations appear in the planetary boundary layer and a crude representation of friction is obtained inducing large dissipation and generation terms. The vertical diffusion scheme is based on a local exchange coefficient method described in Louis (1979) and Louis *et al.* (1981), with a uniform roughness length of 1 mm and a prescribed vertical profile for the mixing length depicted in Table 1.

3.1 The dry basic state.

The dry basic zonal flow is constructed following the approach chosen by C. Freydier when the variable resolution version of Arpege-IFS model (Courtier *et al.*, 1991) was validated. This has been performed by taking an analytic formulation for the zonally symmetric temperature $T(\varphi, p)$. The geopotential $\phi(\varphi, p)$ is then computed for each pressure level by integrating the hydrostatic equation with $\phi = 0$ at the surface. The balanced zonal flow $u(\varphi, p)$ is finally obtained by setting the zonal and meridional wind tendencies to zero. The meridional wind is also set to zero and all the variables (T, ϕ, u) are zonally symmetric (see the Appendix). The result for the basic state is depicted on Fig. 1(a) where a baroclinic zone is centred at 45 °N, with a stationary jet of 30 m s⁻¹ at 200 hPa.

Three simulations EXP-A, EXP-H and EXP-HV are made in order to investigate the life cycle of baroclinic waves. The French Arpege model is used with the same initial state for the three

Figure 2: *Horizontal sections at day 7 in the life cycle for the second and third experiments: (a) and (b) for EXP-H and (c) and (d) for EXP-HV. Sections shown are for: (a) and (c) mean sea level pressure at interval of 5 hPa; (b) and (d) temperature at 900 hPa at interval of 2 K.*

simulations. It is a zonal basic flow with a superimposed most unstable normal mode at zonal wavenumber 8, determined by use of the method of Thorncroft and Hoskins (1990, hereafter TH90). A small random initial perturbation is added to the surface pressure of the basic flow. The nonlinear growth of the perturbation amplitude is followed during the integration of the model until it is exponential to within a specified accuracy. The relative changes in growth rate and the phase speed are computed every hour according to Simmons and Hoskins (1976). The results are shown in Fig. 1(b) where the relative change in growth rate from one hour to another reaches 10^{-4} at day 22 and where the phase speed is close to $5.6 \text{ degrees (day)}^{-1}$ after averaging time oscillations. Note that, according to TH90, the perturbation amplitudes are reduced together for p_s , u , v and T by a common factor when they become too large. At the end of the simulation, the mode is normalized so that the surface-pressure perturbation is 1 hPa, with a common global damping for p_s , u , v and T .

3.2 Baroclinic developments

The surface pressure and temperature at 900 hPa at day 7 are shown in Figs. 2 (a) and (b) for the adiabatic simulation EXP-H. The same fields are presented in Figs. 2 (c) and (d) for the diabatic simulation EXP-HV.

For EXP-H, the pressure trough and cold front are in good agreement with the equivalent results depicted in Fig. 1 of Simmons and Hoskins (1978) when they studied a similar T42 adiabatic simulation with a wave-number-6 perturbation of a 45°N jet. At day 7, the surface pressure lows are about 982 hPa at 55°N , with high pressure reaching 1031 hPa at 42°N . The temperature planetary waves at 900 hPa depicted in (b) are associated with moderate gradients and, as in Fig. 1 of Simmons and Hoskins (1978) or in Fig. 6 of Hoskins and Simmons (1975),

the surface troughs and ridges in Fig. 2 (a) are in phase for all latitudes from 25 °N to 70 °N with the axes of warmest and coldest air in Fig. 2 (b), respectively.

The surface pressure field for the experiment EXP-HV in Fig. 2 (c) is almost identical with the corresponding adiabatic version in Fig. 2 (a), except there is a global smoothing of the field when the vertical diffusion is activated. The pressure lows increase from 982 to 993 hPa, with an overall gradient decrease.

The difference in the temperature field at 900 hPa between EXP-H and EXP-HV is more important in the range of latitude from 45 °N to 60 °N. There is an Eastward shift of about 10 ° of the warm axes and of the occluded part of the front. The fields are more profoundly modified closer to the surface (not shown) where the vertical diffusion scheme is acting.

4 Energetic analysis of the baroclinic waves.

4.1 Practical computations of the available enthalpy cycle.

An output dataset from Arpege is used for the 27 post-processed data on pressure levels, at intervals of 25 hPa from 1000 to 800 hPa, 50 hPa from 800 to 100 hPa and with the four upper levels at 70, 50, 30 and 10 hPa. Time derivatives and other terms of cycle (36) of Part I are evaluated with meteorological data available every 3 h.

The post-processed fields are (u, v, T, ω) for all pressure levels and on the same $1^\circ \times 1^\circ$ latitude \times longitude grid. Vertical and horizontal differencing schemes used in the diagnostic package are second-order centred grid point schemes, different from those used in Arpege where ω values are located on half-levels and where horizontal derivatives are computed in spectral space. The reason why diagnostics have not been computed directly in Arpege with the same numerical schemes is to allow future studies of different models with “pressure levels” and “latitude \times longitude” grid structures as a common starting point for the same diagnostic package.

The modified time scheme described in Part I will be used to solve the generic equations of (36) in Part I, denoted by $\partial_t(Z) = C$. The notations $Z^{(+)}$, $Z^{(-)}$ and $C^{(0)}$ are used for values of Z and C at time $t_0 + \Delta t$, $t_0 + \Delta t$ and t_0 , respectively. The scheme² takes

$$\frac{Z^{(+)} - Z^{(-)}}{2 \Delta t} \approx \frac{C^{(+)} + 4C^{(0)} + C^{(-)}}{6}. \quad (4)$$

For the present ideal case study, the scale-length is equal to the half-wavelength of the normal mode, i.e. $360/16 = 22.5^\circ$. The advection is obtained from day-to-day observations of the mode and the value is different from the theoretical value of $5.6^\circ/\text{day}$, as shown in Fig. 1 (b). The real value is about $7^\circ/\text{day}$. For a time interval of 3 h, the critical time interval is equal to $25/7 \approx 3.2$ days and the value of 3 h is thus far below the corresponding limit of $0.8 \times 3.2 = 2.6$ days required for an accurate application of (4) with an error lower than 0.2 % (see Table 1 in Part I).

4.2 Global results (adiabatic and diabatic simulations).

Evolutions of global energy components of the basic life cycle are presented in Fig. 3 for days 3 to 13 of the simulations EXP-A, EXP-H and EXP-HV. The large computational domain extends vertically from 1000 to 10 hPa and the horizontal limits are 25 °N and 65 °N, 0 °E and 180 °E. Although it is not a real global domain (say 90 °S to 90 °N and 180 °W to 180 °E), it is clear from Figs. 2(a)–(d) that fields are nearly zonally symmetric to north and south of the computational domain and periodic in longitude (there is an even number of planetary waves $m = 8$). Unused

²This scheme is expressed differently in Part I: $C^{(0)} + [C^{(+)} - 2C^{(0)} + C^{(-)}]/6$. The two formulations are clearly equivalent.

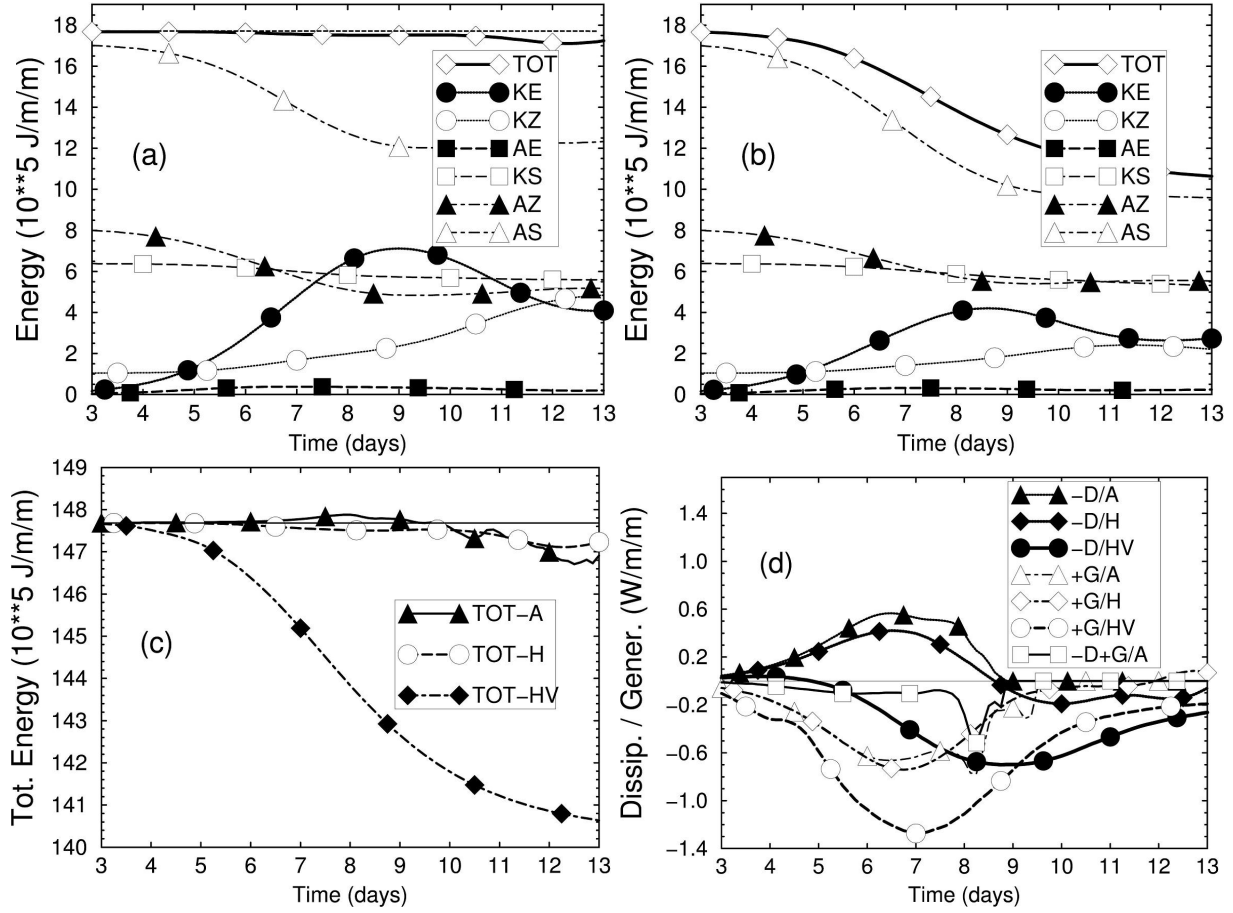

Figure 3: *Evolution of global energy components of the basic life cycle, from day 3 to day 13. (a) Energy components for the simulation EXP-H with the weak ∇^6 horizontal diffusion. Energy are in units of 10^{15} J m^{-2} . The stability component A_S and the total energy $TOT = K_E + A_E + K_Z + A_Z + K_S + A_S$ have had 115 and 130 units subtracted for ease of plotting, respectively. (b) As (a) but for the diabatic simulation EXP-HV with an additional vertical diffusion. (c) Evolution of total energy for EXP-A, EXP-H and EXP-HV. Changes in energy are in units of $W \text{ m}^{-2}$. (d) Evolution of the total dissipation term $-D = -D_E - D_Z - D_S$ and the total generation term $G = G_E + G_Z + G_S$ for the same three simulations as in (c). The sum $-D + G$ is depicted with open square symbol only for the adiabatic simulation EXP-A. Dissipation and generation of energy are in units of $W \text{ m}^{-2}$. See text for explanation.*

parts of this global domain would not have contributed significantly to energetics of the simulations and it is expected that, for this large computational domain, the baroclinic or barotropic signals will be enhanced and be easier to analyse than for the real global domain.

Global energy components for the simulation EXP-H are presented on Fig. 3 (a). As expected the total energy TOT is a constant up to day 10 for this adiabatic case. The rapid increase of KE is maximum at day 6.5 and KE reaches its maximum value at day 9 ($+7.10^{15} \text{ J m}^{-2}$). There is a slow and less important increase in KZ in the growing stage of the mode, followed by a more rapid increase between days 9.5 and 12 when KE start to decrease and when the mode decays. The initial increase in KE and KZ up to day 9 is thus obtained at the expense of AS and AZ , via possible baroclinic processes to be confirmed later on. The rapid increase of KZ in the depletion stage is realized at the expense of KE , because only KZ and KE vary in time after day 9. This transfer of energy from KE to KZ is usually considered as a barotropic conversion. As for the changes in the global components AE and KS , they are less than $\pm 1.10^{15} \text{ J m}^{-2}$ and do not give contributions to the global energetics. All these global results are similar to those reported in the “T42” study of Pearce (1978, hereafter P78) and in the “T95” study of TH90, with almost the same time-scale and the same intensity as in P78, whereas in TH90 the growth

of KE is more rapid with a maximum value for KE reaching $11 \cdot 10^5 \text{ J m}^{-2}$ at day 6.5.

Figure 3 (b) shows the results for the diabatic simulation EXP-HV including the vertical diffusion scheme. In comparison with EXP-H, the total energy decreases continuously during the 13 days of the simulation. The decrease in the global static stability component AS is more important. It is a direct impact of the vertical mixing, leading to a decrease in the low-level vertical gradients of temperature (not shown). Another important feature is that the increases in KE and KZ are smaller than for EXP-H. The effect of smoothing the horizontal gradients of the fields, already mentioned in the comments of Fig. 2, is confirmed by the energetic analysis and it leads to smaller values for KE and KZ at each stage of the simulation. Changes in KS and AE are small (less than $\pm 1 \cdot 10^5 \text{ J m}^{-2}$), as for EXP-H.

Total energy TOT is a constant for EXP-A in Fig. 3 (c), with, however, a small and unrealistic increase above the initial value during the growing stage of the mode (from days 6 to 9). Values of TOT for EXP-H are also nearly constant but they lead to a more realistic continuous and small decrease, indicating that the explicit ∇^6 horizontal diffusion has a small but positive global impact on the total energy. The e-folding times for horizontal diffusion are short enough to suppress the noisy features at high zonal wavenumber and do not lead to excessive numerical flattening of the fields that could induce spurious changes in total energy. Relative changes of TOT are less than 0.2 % up to day 10 for the two adiabatic simulations and absolute changes are less than $\pm 0.25 \cdot 10^5 \text{ J m}^{-2}$. As expected, they are small in comparison with the gain in eddy kinetic energy ($+7 \cdot 10^5 \text{ J m}^{-2}$) and they can be compared with the small changes in AE or KS .

Global dissipation and generation terms are depicted on Fig. 3 (d) for the three simulations and the difference $G - D$ is plotted only for EXP-A with the open square symbol. It is expected from (3) that, for a nearly constant total energy and for zero boundary fluxes, $G - D$ must be small. Absolute values are indeed lower than 0.1 W m^{-2} up to day 8, whereas D and G reach $\pm 0.6 \text{ W m}^{-2}$ for the adiabatic cases. This result is another global validation for the cycle (3), indicating that no global terms are missing and that the numerical computations are accurate enough. Although the dissipation is positive for EXP-A and EXP-H, the behaviour for the diabatic simulation EXP-HV is more realistic. There is a negative global dissipation (dark circle) reaching -0.7 W m^{-2} at day 9 and a negative generation (open circle) reaching -1.3 W m^{-2} at day 7. These negative and large generations and dissipations for EXP-HV explain the decreasing of AS in Fig. 3 (b) and the moderate increase in KZ and KE .

4.3 Local results for $\overline{k_E}$ (adiabatic simulation).

Results for the large computational domain (25°N – 65°N ; 0° – 180°E) are presented in Fig. 4 for the eddy kinetic energy and for the adiabatic simulation. According to formulation (36) of the cycle of Part I, the reservoir $\overline{k_E}$ is connected to $\overline{k_Z}$ and $\overline{a_E}$ by the barotropic and baroclinic conversions $\overline{c_K}$ and $\overline{c_E}$, respectively. The intensity of these conversions will be evaluated with the aid of pressure-time diagrams. The new direct conversion with $\overline{\phi}$, denoted by $-\overline{B(\phi)_E}$, and the dissipation $-\overline{d_E}$ must also be carefully investigated.

There are two maximum values for $\overline{k_E}$ in Fig. 4 (a) at day 9. The first maximum is located just below the jet at 250 hPa and the other one is located at the surface. A relative minimum is observed up to day 10 in the middle troposphere between 800 and 500 hPa.

Figures 4 (b)–(f) are expressed with a common unit of $10^{-5} \text{ W kg}^{-1}$. The total change in time $\overline{\partial_t(k_E)} + \overline{B(k_E)}$ is depicted in (b) including the boundary flux term, with observed small values for $\overline{B(k_E)}$ (not shown). The maximum and minimum values are located, as for Fig. 4 (a), at the surface and at about 250 hPa (at days 6.5 for the maximum and at day 11 for the minimum).

The equation for $\overline{\partial_t(k_E)}$ corresponds in Fig. 4 to: (b) = (c) + (e) + (f) + (d). An expected result is that the dissipation in Fig. 4 (d) for such an adiabatic simulation should be small in comparison with others terms Figs. 4 (b), (c), (e) and (f), for all levels and at any time. And

Figure 4: Time–pressure diagrams from day 2 to day 13 of the adiabatic simulation *EXP-H* with the ∇^6 horizontal diffusion and for the eddy kinetic energy reservoir. The horizontal domain extends from 25°N to 65°N in latitude and it includes all the longitudes from 0 to 180° . The isopleths ± 4 , ± 10 and ± 20 are annotated, followed by the contoured isopleths ± 40 , ± 100 , ± 200 , ± 400 and ± 1000 . (a) The component $\overline{k_E}$ (J kg^{-1}). (b) The total budget $\partial_t(\overline{k_E}) + B(\overline{k_E})$: it is the sum of the local time derivative plus the divergence of boundary flux. (c) The usual baroclinic conversion $\overline{c_E}$. (d) The dissipation term $-\overline{d_E}$, expressed as a residual of the equation for $\partial_t(\overline{k_E})$ in Eqs. (36) of Part I. (e) The usual barotropic conversion $\overline{c_K}$. (f) The direct conversion term $-B(\Phi)_E$, between Φ and $\overline{k_E}$. Units are $10^{-5} \text{ W kg}^{-1}$ for (b)–(f). See text and Appendix A of Part I for explanation of symbols.

indeed, the isopleths for ± 5 units appear only in Fig. 4 (d) at the levels and at the moment when absolute changes in $\overline{k_E}$ are maximum in Fig. 4 (b). Therefore, the dissipation for this adiabatic simulation is only due to errors in the numerical schemes already mentioned. It is demonstrated that, on a local stage, there are no missing terms in (36) of Part I because, in that case, any forgotten or approximated terms would have contributed with an opposite sign to the residual $-\overline{d_E}$ in Fig. 4 (d).

Figure 4 (b) shows a growing stage of the eddy kinetic energy from day 4 to day 9, associated with a large domain of positive values visible from the surface up to 150 hPa, followed by a depletion stage corresponding to negative values after day 9. These growing and decreasing stages for $\overline{k_E}$ are usually associated with baroclinic and barotropic developments, respectively. However, if the baroclinic and barotropic conversions in Fig. 4 (c) and (e) have the correct sign to partly explain the total change of $\overline{k_E}$ in Fig. 4 (b), direct comparisons of Figs. 4 (c) and (b) show that the fields are out of phase.

Maximum values observed in the middle troposphere for $\overline{c_E}$ correspond to minimum values in

Fig. 4 (b). Similarly, maximum values for the total change in Fig. 4 (b) close to the jet and at the surface are associated with small values of $\overline{c_E}$.

A possible explanation for the difference between Figs. 4 (b) and (c) is to consider that the term $-\overline{B(\phi)_E}$ in Fig. 4 (f) exports the positive middle-troposphere baroclinic input of energy toward the surface and the jet. This mechanism has been described in Orlandi and Sheldon, 1995 (hereafter referred to as OS95) as vertical redistributions of energy via work done by pressure forces. It is also in agreement with the fact that Fig. 4 (f) is neglected in global study of L55 because vertical redistributions correspond to small or zero integral values over the depth of the atmosphere (not shown).

Figure 4 (f) shows a complex pattern for the vertical redistribution term $-\overline{B(\phi)_E}$. Positive values close to the surface are the main source for the developments of the mode. It is true for the maximum of +42 units observed at day 6.5 in Fig. 4 (b) which is partitioned into +3 units from $-\overline{d_E}$ in Fig. 4 (d), +5 units from $\overline{c_K}$ in Fig. 4 (e), +11 units from $\overline{c_E}$ in Fig. 4 (c) and +23 units from $-\overline{B(\phi)_E}$ in Fig. 4 (f). The larger term is the positive vertical redistribution Fig. 4 (f) rather than the baroclinic conversion.

Negative values in the middle troposphere for Fig. 4 (f) are almost balanced by the baroclinic conversion Fig. 4 (c). This baroclinic conversion cancels out above the 250 hPa level and the positive values between 350 and 100 hPa for $-\overline{B(\phi)_E}$ are the only contribution among Figs. 4 (c), (d), (e) or (f) that can explain the growth of $\overline{k_E}$ for the stratospheric part of the jet (above the level 250 hPa). Therefore the direct conversion between $\overline{\phi}$ and $\overline{k_E}$ plays a major role in energetics of stratospheric circulations when $\overline{k_E}$ is considered.

The barotropic conversion $\overline{c_K}$ in Fig. 4 (e) partly explains the depletion stage of the mode, with negative values for the jet and in the boundary layer after day 9. However negative values after day 9 in Figs. 4 (d) and (f) are two other contributions for the decrease in $\overline{k_E}$. As for the positive values for $\overline{c_K}$ in the boundary layer from day 6 to day 9, they could be interpreted as a barotropic instability. Nevertheless, this explanation will not be confirmed for EXP-HV when the vertical diffusion scheme is activated. These spurious barotropic instabilities are the result of a lack of surface dissipation in adiabatic simulations.

4.4 Local results for $\overline{k_E}$ (diabatic simulation).

Results for the diabatic simulation EXP-HV with both horizontal and vertical diffusions acting together are presented on Fig. 5 for $\overline{k_E}$. When comparing EXP-H and EXP-HV, the differences are not important for the total change in Fig. 5 (a) for the upper troposphere (above the 600 hPa level) and close to the jet. Differences are more important in the boundary layer between 1000 and 900 hPa when they are associated with the vertical diffusion scheme. The maximum of $\overline{k_E}$ occurs at day 7.5, two days ahead in comparison with EXP-H. The maximum growth of the mode in Fig. 5 (b) has decreased from 42 to 17 units in the boundary layer with respect to Fig. 4 (b). A vertical displacement of this maximum is observed for the diabatic simulation: it rises from the surface to 975 or 950 hPa levels (the first diagnostic pressure levels).

Even if general characteristics are left unchanged between Figs. 4 (c) and 5 (c), baroclinic conversions decrease for all days and for all levels when the vertical diffusion is activated. There are large values (≈ 35 units) in the middle troposphere, with small values close to the surface and at the levels above 250 hPa. As for the barotropic conversion, comparisons of Figs. 4 (e) and 5 (e) show large modifications occurring below the level 800 hPa, where the unrealistic positive and negative maximum observed at days 8 and 11 for EXP-H disappear. The result is a barotropic decrease of the mode for the jet after day 9, but with no equivalent barotropic stabilisation close to the surface. As a consequence, the decrease of the mode in the boundary layer after day 8.5 in Fig. 5 (b) must be explained by non-barotropic components, i.e. the dissipation $-\overline{d_E}$ and/or the conversion $-\overline{B(\phi)_E}$.

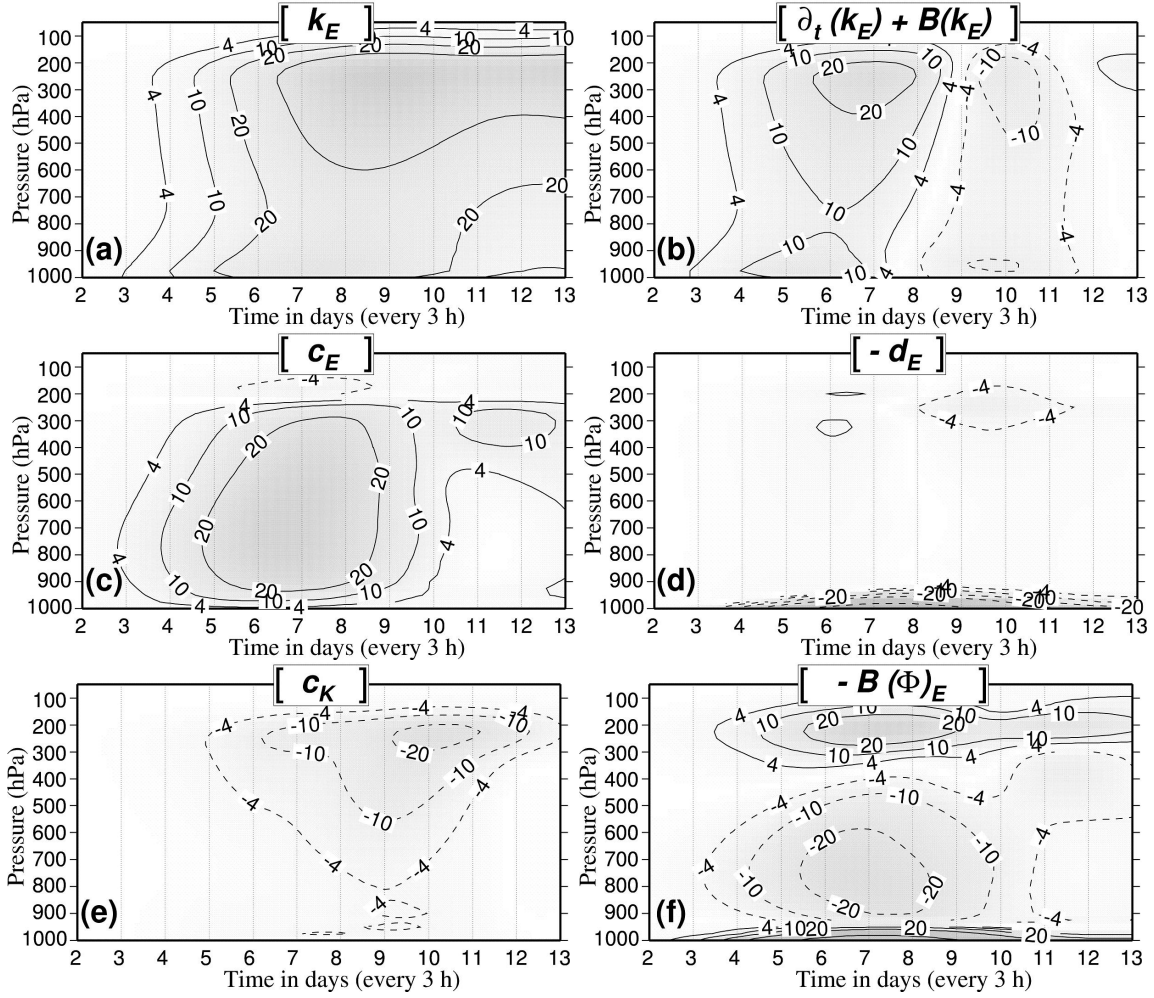

Figure 5: As Fig. 4 and for $\overline{k_E}$ see text), with the same domain, interval and units, but for the diabatic simulation EXP-HV. Both the horizontal and the vertical diffusion act on wind and temperature. The equation for $\overline{k_E}$ corresponds to (b) = (c) + (e) + (f) + (d). The numerous isopleths located near the surface in (d) and (f) correspond to real large negative values for the dissipation (d) and large positive values for the conversion (f). The annotated isopleths are ± 4 , ± 10 and ± 20 , followed by the contoured isopleths ± 40 , ± 100 , ± 200 , ± 400 and ± 1000 .

Although the dissipation is, as expected, weak at all levels for the adiabatic simulation in Fig. 4 (d), large negative values are observed in Fig. 5 (d) in the boundary layer (≈ -150 units). They correspond to large and expected dissipations created by the vertical diffusion scheme and by the surface friction. As in EXP-H, values for $-\overline{d_E}$ above the level 900 hPa where the vertical diffusion is not active are small in comparison with those in Figs. 5 (b), (c), (e) and (f). It is a local validation for the cycle (36) of Part I, obtained for the diabatic simulation in the free atmosphere.

The validation of large values for $-\overline{d_E}$ in Fig. 5 (d) must be carefully realized. Indeed, many authors have obtained similar large dissipation terms computed as residuals and associated with large boundary terms $-\overline{B(\phi)_E}$ (Muench 1965, Brennan and Vincent 1980, Michaelides 1987). They consider these large dissipation terms as not reliable. However, in this diabatic study, it seems that large negative values for $-\overline{d_E}$ in the boundary layer are balanced by large positive counterparts observed for $-\overline{B(\phi)_E}$ in Fig. 5 (f). The sum of Figs. 5 (d) and (f) is presented in Fig. 6 (a). The balance between $-\overline{d_E}$ and $-\overline{B(\phi)_E}$ is established close to the surface, leading to moderate positive values up to day 8 for the sum ($\leq +12$ units), whereas they reach ± 150 units separately.

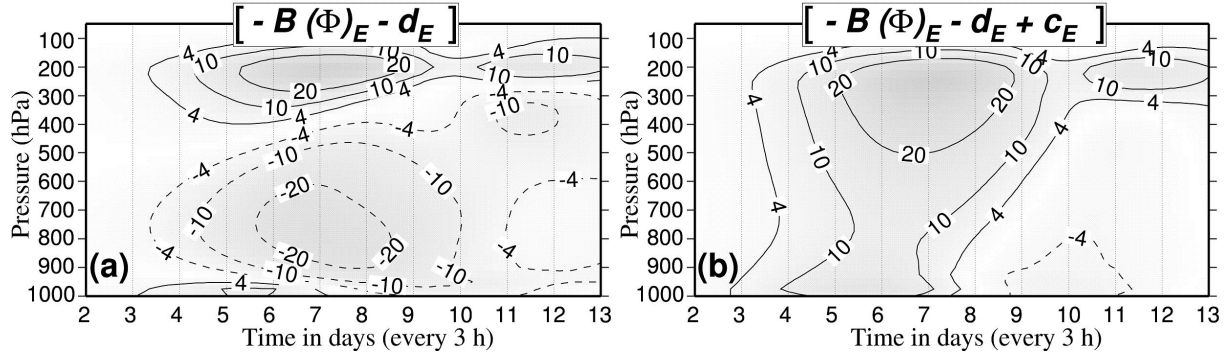

Figure 6: Time–pressure diagrams from day 2 to day 13 for the same simulation EXP-HV as in Fig. 5. (a) The sum $-\overline{B(\phi)_E} - \overline{d_E}$. (b) The sum $-\overline{B(\phi)_E} - \overline{d_E} + \overline{c_E}$. See text for explanation.

The equation for $\overline{k_E}$ in (36) of Part I can be further modified by adding the baroclinic conversion $\overline{c_E}$ to the sum $-\overline{B(\phi)_E} - \overline{d_E}$, to give the non-barotropic part of the total change of $\overline{k_E}$ depicted in Fig. 6(b). If the barotropic part in Fig. 5 (e) is easy to interpret, the non-barotropic part in Fig. 6 (b) is a new combination of terms. As explained in (49) of Part I, it is the sum of the eddy dissipation $-\overline{d_E}$ plus the work of eddy part of the pressure force, leading to

$$-\overline{B(\phi)_E} + \overline{c_E} - \overline{d_E} = -\overline{(\mathbf{U}_h)_\lambda \cdot (\nabla_p \phi)_\lambda} - \overline{d_E}. \quad (5)$$

The depletion stage of the mode is represented by negative values in the boundary layer after day 8 in Fig. 5 (b). A surprising result is that this decreasing of the mode is not exclusively due to the barotropic conversion $\overline{c_E}$ in Fig. 5 (e). It is also a consequence of the negative values observed in the boundary layer for the non-barotropic part defined by (5). The maximum of -12 units at day 10 close to 950 hPa in Fig. 5 (b) is separated into -4 units for $\overline{c_E}$ in Fig. 5 (e) and -8 units in Fig. 6 (b). The non-barotropic part is thus the largest term.

By defining (5), a cancellation of the baroclinic conversion is obtained and, similarly to OS95, divergence of ageostrophic geopotential fluxes appear to be the main feature in local energetics of baroclinic systems. Indeed, (5) can be interpreted as an equilibrium between the dissipation and the energetic impacts of ageostrophic circulations. The computations of the eddy terms in (5) are done with a zonally symmetric Coriolis term, leading to $(f)_\lambda = 0$. The result is that the eddy part of the pressure force may be written as

$$-(\nabla_p \phi)_\lambda = f \mathbf{k} \times (\mathbf{U}_g)_\lambda.$$

The eddy conversion term then becomes

$$-\overline{(\mathbf{U}_h)_\lambda \cdot (\nabla_p \phi)_\lambda} = \mathbf{k} \cdot \overline{f (\mathbf{U}_g)_\lambda \times (\mathbf{U}_h)_\lambda}.$$

Using both $(\mathbf{U}_h)_\lambda = (\mathbf{U}_a)_\lambda + (\mathbf{U}_g)_\lambda$ and the property $(\mathbf{U}_g)_\lambda \times (\mathbf{U}_g)_\lambda \equiv 0$ and without loss of generality, (5) depicted in Fig. 6 (b) can thus be rewritten as

$$\mathbf{k} \cdot \overline{f (\mathbf{U}_g)_\lambda \times (\mathbf{U}_a)_\lambda} - \overline{d_E}.$$

There is a conversion if the ageostrophic wind $(\mathbf{U}_a)_\lambda$ is different from zero and if it not parallel to $(\mathbf{U}_g)_\lambda$. However, this formulation differs from the vertical redistribution of energy described in OS95 paper because it is not a divergence of some ageostrophic geopotential fluxes, in the form $\overline{\nabla_p(\phi \mathbf{U}_h)_a}$, for instance.

4.5 Integral results for $\overline{k_E}$ (diabatic simulation).

The five “time–pressure” diagrams (Figs. 5 (b)–(f)) exhibit complex patterns, with several minimum and maximum values located at different levels. It seems worthwhile, however, to investigate

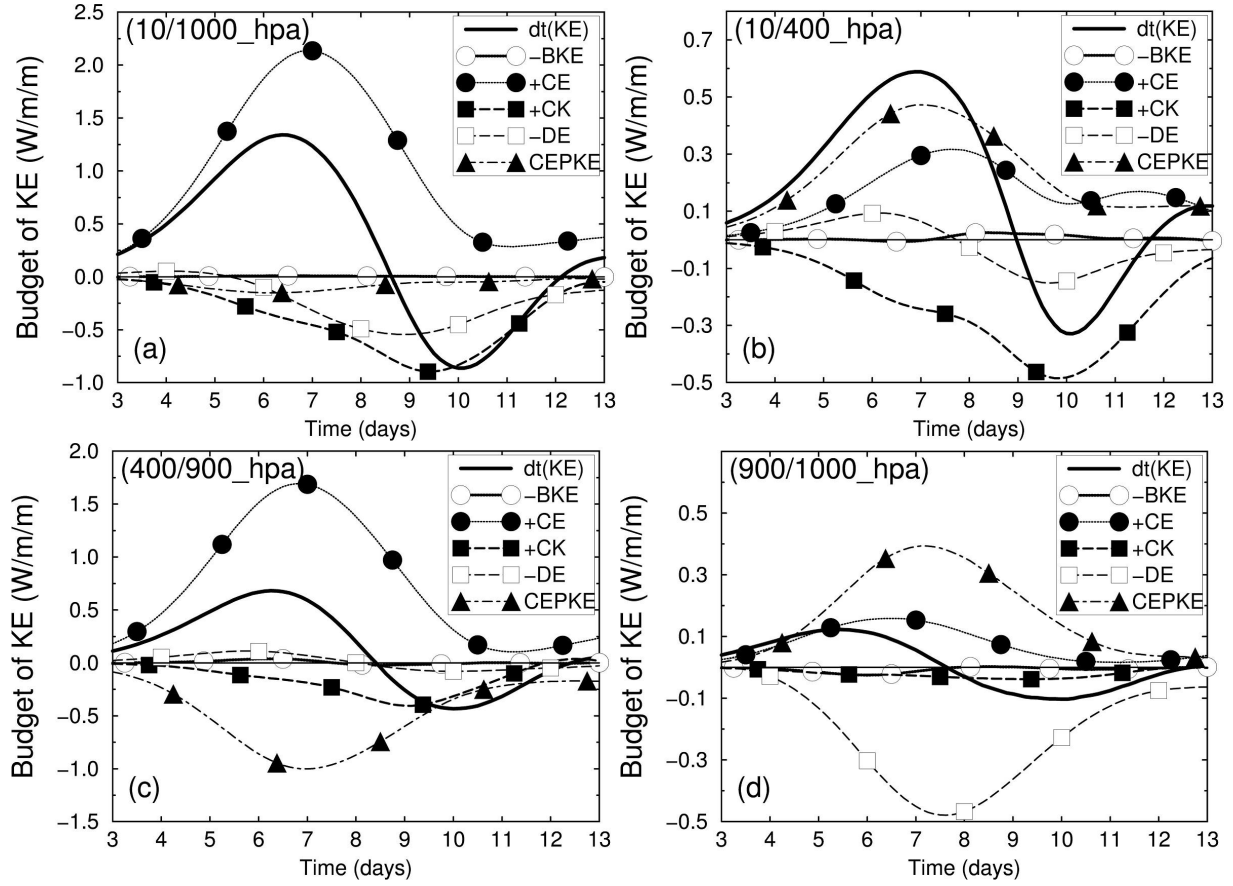

Figure 7: Vertical integrals of budget equation for $\overline{k_E}$ (W m^{-2}). Terms are computed for the diabatic simulation EXP-HV and for four layers. Tendencies $\partial_t \overline{k_E}$, denoted by $dt(KE)$ in the figure (thick solid line); boundary terms $-\overline{B(k_E)}$, denoted -BKE (open circles and solid line); baroclinic conversions $\overline{c_E}$, denoted +CE (dark circles and thin solid line); barotropic conversions $\overline{c_K}$, denoted CK (dark squares and thick dashed line); dissipation terms $-\overline{d_E}$, denoted -DE (open squares and thin dashed line); conversion terms with potential energy $-\overline{B(\phi)_E}$, denoted CEPKE (dark triangles and mixed dashed line). (a) 10 to 1000 hPa (global case). (b) 10 to 400 hPa (stratosphere and jet). (c) 400 to 900 hPa (middle troposphere). (d) 900 to 1000 hPa (planetary boundary layer).

the budget equation for $\overline{k_E}$ for three homogeneous layers: (i) the planetary boundary layer (from 1000 to 900 hPa), (ii) the middle troposphere (from 900 to 400 hPa) and (iii) the stratosphere and the jet (400 to 10 hPa). A fourth global layer will also be considered: the integral from 1000 to 10 hPa corresponding to the global available-enthalpy cycle.

The global case is presented in Fig. 7 (a) for EXP-HV. As expected, the increase in $\overline{k_E}$ up to day 8.5 (positive values for the tendencies) is mainly controlled by the positive baroclinic conversion, with smaller negative contributions produced by the barotropic conversion and the dissipation terms. The boundary term $-\overline{B(k_E)}$ is very small and it is not considered in the global studies (L55, P78).

The additional global conversion $-\overline{B(\phi)_E}$ denoted by CEPKE in Fig. 7 (a), is smaller than other terms (except $-\overline{B(k_E)} = -\overline{B(k_E)} \approx 0$). It is usually neglected in global studies (L55 and P78). However it reaches -0.2 W m^{-2} at day 6, a value equal to half the barotropic conversion in the growing stage of the mode. As already mentioned in Part I, this term is not a real boundary term, i.e. $-\overline{B(\phi)_E} \neq -\overline{B(\phi_E)}$, and its vertical integral must not cancel out. Locally observed large values of $-\overline{B(\phi)_E} = \text{CEPKE}$ in Fig. 5 (f) and small corresponding global values of CEPKE in Fig. 7 (a) lead to a justification for the concept of vertical redistribution of energy described in OS95 (see sections 4.3 and 4.4). As a consequence, $-\overline{B(\phi)_E}$ should appear both in local and global studies.

The budget of $\overline{k_E}$ for the middle troposphere in Fig. 7 (c) is almost similar to the global case, although observed negative values of CEPKE are much larger according to the large negative region in Fig. 5 (f). Another difference is that the dissipation is very small, owing to the distance from the jet and from the surface where eddy diffusion and ageostrophic circulations occur preferentially. Clearly, the barotropic and the baroclinic terms alone cannot explain the budget of $\overline{k_E}$. In the middle troposphere, the leading terms are $\overline{c_E}$, $-\overline{B(\phi)_E}$ and $\overline{c_K}$, in decreasing order.

In the stratosphere and for the jet, the growing stage of the mode in Fig. 7 (b) correspond to a balance between positive barotropic and negative baroclinic components. The additional vertical redistribution term $-\overline{B(\phi)_E}$ is positive and it is the largest term up to day 9. Like the baroclinic conversion $\overline{c_E}$, it can explain the increase of $\overline{k_E}$. The small eddy dissipation $-\overline{d_E}$ is positive and then negative, reaching $+0.1 \text{ W m}^{-2}$ at day 6 and -0.15 W m^{-2} at day 10, like for the middle troposphere case.

As expected, the depletion stage of the mode after day 9 in Figs. 7 (a) and (b) corresponds to global negative values for the dissipation and for the barotropic conversion. However the decrease of $\overline{k_E}$ after day 9 for the middle troposphere in Figs. 7 (c) is caused by negative values for barotropic conversion and $-\overline{B(\phi)_E}$, with a very small contribution from eddy dissipation.

In the planetary boundary layer, changes in $\overline{k_E}$ in Fig. 7 (d) correspond to positive values for the baroclinic conversion, at least up to day 6. But the dominant feature in this diagram is the balance between the large terms $-\overline{B(\phi)_E}$ and $-\overline{d_E}$. Results derived in section 4.4 show that the total balance between the three terms is equal to $\mathbf{k} \cdot \overline{f(\mathbf{U}_g)_\lambda \times (\mathbf{U}_a)_\lambda} - \overline{d_E}$. The depletion stage of the mode is due to observed negative values in the Ekman layer for this total balance, because the effect of ageostrophic circulations and eddy dissipation do not exactly compensate each other. This is only true for the Ekman spiral.

4.6 Ekman dissipation for diabatic simulations.

Explanations for the balance between large positive and negative values for

$$-D = \mathbf{U}_h \cdot \mathbf{F}_h \quad \text{and} \quad C_a = -\mathbf{U}_h \cdot \nabla_p(\phi),$$

as observed in the boundary layer in Figs. 5 (d), 5 (f) and 7 (d), are given in this section. It is demonstrated that the two terms have opposite signs with exactly the same magnitudes in the case of an idealized Ekman spiral, in which case the non-barotropic part (5) is zero in the boundary layer.

If the horizontal wind and the frictional force are expressed in the complex form

$$V = u + i v \quad \text{and} \quad F_h = (F_h)_y + i (F_h)_x,$$

the dissipation is equal to the real part $-D = \Re(\overline{V} F_h)$ and it can be verified that the conversion term due to the ageostrophic wind is equal to $C_a = \Im(f \overline{V}_g V_a)$, where the overbars represent complex conjugates.

In complex formulation, the Ekman spiral frictional force due to the vertical dissipation scheme is given by $F_h = i f V_a$ and for this value the dissipation due to the vertical diffusion is exactly compensated by the conversion created by ageostrophic secondary circulations, or equivalently

$$D = C_a = f (u_g v_a - v_g u_a) = f \mathbf{k} \cdot (\mathbf{U}_g \times \mathbf{U}_a).$$

The common value for $C_a = D$ can be computed by using the Ekman spiral for a general surface angle θ and for a height of planetary boundary layer given by H_{pbl} . In complex form, the ageostrophic wind is written

$$V_a = V_g \sqrt{2} \sin(\theta) \exp\left(-\frac{\pi z}{\Lambda}\right) \exp\left[i \pi \frac{(H_{pbl} - z)}{\Lambda}\right], \quad (6)$$

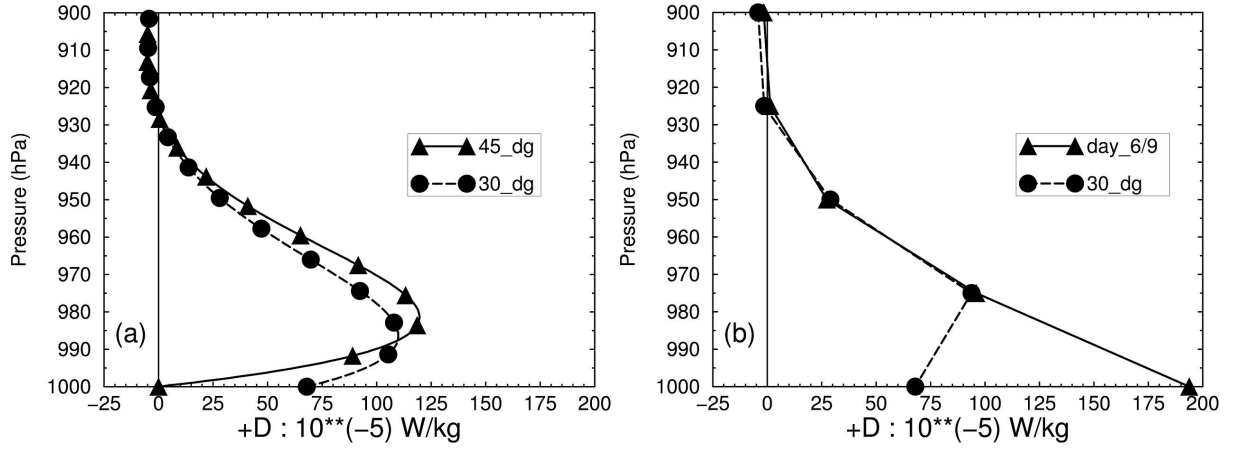

Figure 8: Positive values of $+D > 0$ for idealized Ekman spirals and within the boundary layer ($-D$ is the usual negative dissipation). (a) Two theoretical spirals with the surface angle $\theta = 45^\circ$ and $\theta = 30^\circ$. A refined vertical resolution of 400 levels is used. (b) The theoretical spiral with $\theta = 30^\circ$ and the averaged observed values from day 6 to day 9 for the diabatic simulation EXP-HV. There are four vertical levels above the 1000 hPa surface pressure, corresponding to the interval of 25 hPa between the constant post-processed pressure levels (975, 950, 925 and 900 hPa).

where the scale height $\Lambda = H_{pbl}/(\theta/\pi + 3/4)$ equals H_{pbl} for the zero surface wind case $\theta = \pi/4$; it becomes smaller than H_{pbl} for decreasing θ and increasing surface wind (ex. $\Lambda \approx 0.917 H_{pbl}$ for $\theta = \pi/6 = 30^\circ$). The conversion is computed by using (6) and $C_a = \Im m(f \bar{V}_g V_a)$, to give

$$C_a = D = f (V_g)^2 \sqrt{2} \sin(\theta) \exp\left(-\frac{\pi z}{\Lambda}\right) \sin\left[\pi \frac{(H_{pbl} - z)}{\Lambda}\right]. \quad (7)$$

The maximum value for C_a is obtained by cancelling the derivative with respect to $Z = z/\Lambda$ of the function $f(Z) = \exp\{-\pi Z\} \sin\{\pi (H_{pbl}/\Lambda - Z)\}$. The height for this maximum is equal to $z_{max} = \Lambda/4 + (H_{pbl} - \Lambda)$. For $\theta = \pi/n$, this expression reduces to $z_{max} = H_{pbl}/\{4 + 3(n - 4)/4\}$. It gives $z_{max} = 0.25 H_{pbl}$ for $n = 4$ (latitude 45°), $z_{max} \approx 0.182 H_{pbl}$ for $n = 6$ (latitude 30°) and $z_{max} \approx 0.143 H_{pbl}$ for $n = 8$ (latitude 22.5°).

Examples of different dissipation terms ($+D > 0$) for idealized Ekman spirals are presented in Fig. 8 (a) for two surface angles ($\theta = 45^\circ$ and $\theta = 30^\circ$) and with a high vertical resolution. The height of the maximum for $+D$ is lower for the case 30°N , in agreement with the values $0.25 H_{pbl}$ and $0.182 H_{pbl}$ for 45°N and 30°N , respectively.

Equation (7) is used with a height of the boundary layer set to $H_{pbl} = 600$ m, corresponding to the pressure 928 hPa where the dissipation cancels out on Fig. 8 (b). The Coriolis parameter for an average latitude of 45°N is set to 10^{-4} s^{-1} and the module of the geostrophic wind is set to 6 m s^{-1} .

Figure 8 (b) shows the successful fitting between the idealized Ekman spiral ($\theta = 30^\circ$) and the averaged observed values from day 6 to day 9 for the diabatic simulation EXP-HV depicted on Fig. 5 (d). Dissipations in the free atmosphere above the level 928 hPa are small and $-D$ is positive as predicted by the Ekman spiral. Below the level 928 hPa, the observed and theoretical curves can be superposed at 950 and 975 hPa. However the fitting cannot be obtained for the level 1000 hPa because this level is subject to several errors. Firstly the 25 hPa post-processed level interval is coarser than the uneven model levels interval, equal to 13 and 24 hPa for the first ones. As a consequence the vertical differencing schemes differ. Secondly, there are interpolations and/or extrapolation of the fields for the case of surface pressure greater and/or lower than 1000 hPa, with the side effect of excluding or including unrealistic or fictitious mass of atmosphere into the energetic budget.

This interpretation of large local values for atmospheric dissipation expressed as residuals is

an important result of this paper. It is the ultimate local validation of the available-enthalpy cycle (36) of Part I, giving the proof that there are no approximate or missing terms. However, the real ageostrophic circulations diverge from the idealized Ekman spiral case, because the eddy coefficients are not independent of height. It is the reason why the sum (5) depicted in Fig. 6(b) is not exactly zero and imbalances between $\mathbf{k} \cdot \overline{f(\mathbf{U}_g)_\lambda \times (\mathbf{U}_a)_\lambda}$ and $-\overline{d_E}$ yield positive values in the growing stage of the mode, with observed maximum values in the boundary layer (975 hPa). As for the maximum values below the jet in Fig. 6 (b), they must be interpreted in term of a balance between effects of ageostrophic circulations and the baroclinic conversion, because the dissipation is very small in this region (see Fig. 5).

4.7 Local results for $\overline{a_E}$ and $\overline{k_S}$ (diabatic simulation).

The equation for $\overline{a_E}$ in the cycle (36) of Part I is similar to the equation for $\overline{k_E}$, but with different conversion terms and a generation term in place of the dissipation. There is no term equivalent to $-\overline{B(\phi)_E}$. Observed values for $\partial_t(a_E)$, $\overline{B(a_E)}$ and $\overline{g_E}$ are small (not shown). They are less than ± 4 units of 10^{-5} W kg $^{-1}$, for all levels and for the whole simulation from day 2 to 13. As a consequence, there is a close balance $\overline{c_A} \approx \overline{c_E}$ and the eddy available enthalpy reservoir $\overline{a_E}$ behaves like a catalytic component. There is a direct transfer of energy from $\overline{a_Z}$ toward $\overline{k_E}$ through $\overline{a_E}$, with no change in $\overline{a_E}$.

The analysis of all terms in the equation for $\overline{k_S}$ (results not shown) reveal that the external path “ $\overline{c_S}$ ” and “ $-\overline{B(\phi)_S}$ ” is the main feature in the troposphere, with large and opposite values leading to $\overline{c_S} - \overline{B(\phi)_S} \approx 0$. There is a catalytic behaviour for $\overline{k_S}$, with a direct transfer of energy via the external path $\overline{a_S} \leftrightarrow \overline{k_S} \leftrightarrow \overline{\phi}$. In the stratosphere, values for $\partial_t(k_S)$, $\overline{B(k_S)}$, $\overline{B(k_{cS})}$, $\overline{c_{KS}}$ and $-\overline{d_S}$ are very small and the balance of terms is somewhat different. The decrease of $\overline{k_S}$ close to the jet (-8 units) is explained by negative ageostrophic redistribution terms $\overline{c_S} - \overline{B(\phi)_S} \approx -22$ units and by $\overline{B(k_{cS})} \approx +16$ units.

4.8 Local results for $\overline{k_Z}$ (diabatic simulation).

The budget for the zonal component $\overline{k_Z}$ is depicted in Fig. 9 (a). Initial values of the zonal wind described in Fig. 1 (a) lead to maximum values for $\overline{k_Z}$ from 100 to 300 hPa, with small values in the lower troposphere. A comparison with the eddy component $\overline{k_Z}$ depicted in Fig. 5 (a) shows that maximum values appear 2 days later in the boundary layer, when $\overline{k_E}$ has reached its maximum or starts to decrease. A delay of 3 to 3.5 days is also observed close to the jet. The total change in time of $\overline{k_Z}$ in Fig. 9 (b) is computed including the two boundary terms $\overline{B(k_Z)}$ and $\overline{B(k_{cZ})}$, with (b) = (c) + (d). The two divergence terms for Fig. 9 (b) are small with respect to $\partial_t(k_Z)$ (not shown). The total change is maximum at day 7 in the boundary layer (950 hPa) and it is maximum at day 10 just below the jet (from 300 to 400 hPa). The delay observed in Fig. 9 (b) in comparison with Fig. 5 (b) is 1 day in the boundary layer and 3 days just below the jet.

The barotropic conversion $-\overline{c_K}$ in Fig. 9 (c) can partly explain the growth of $\overline{k_Z}$ just below the jet, but the positive values for $-\overline{c_K}$ are too large and occur too early in the simulation. They are also located at elevations that are too high (from 150 to 300 hPa). In the boundary layer, the barotropic conversion cannot explain the growth of $\overline{k_Z}$ because there is no significant maximum in Fig. 9 (c) between days 6 and 8. As a result, the change in zonal kinetic energy component is improperly determined by the barotropic conversion term.

The same method used for $\overline{k_E}$ is applied to $\overline{k_Z}$ in order to define and give explanations to a non-barotropic part for $\partial_t(k_Z)$. The dissipation $-\overline{d_Z}$, the conversion with the potential energy $-\overline{B(\phi)_Z}$ and conversions terms $\overline{c_Z}$ and $\overline{c_{KS}}$ are added altogether to form the non-barotropic term depicted in Fig. 9 (d). The conversion $\overline{c_{KS}}$ (not shown) is very small in comparison with other

Figure 9: As Fig. 5, with the same large computational domain and for the diabatic simulation *EXP-HV*, but for the zonal kinetic energy component $\overline{k_Z}$. (a) The component $\overline{k_Z}$. (b) The total budget $\partial_t(\overline{k_Z}) + B(\overline{k_Z} + \overline{k_{cZ}})$: it is the sum of the local time derivative plus the divergence of two boundary fluxes. The budget of $\overline{k_Z}$ writes $(b) = (c) + (d)$. (c) The usual barotropic conversion $-\overline{c_K}$. (d) The non-barotropic part of the budget for $\overline{k_Z}$, equal to the sum $-\overline{B(\phi)_Z} - \overline{d_Z} + \overline{c_Z} + \overline{c_{KS}}$.

terms. Large negative values observed in Fig. 9 (d) for the jet are due to $-\overline{B(\phi)_Z}$ (not shown). They correspond to positive values of $-\overline{c_K}$ for the jet, and the balance between these opposite terms explains why the growth in barotropic conversion is inhibited before day 8 from 500 to 150 hPa. In the boundary layer, the non-barotropic term explains entirely the growth in $\overline{k_Z}$, due to a balance between large negative values for $-\overline{d_Z}$ and large positive values for $-\overline{B(\phi)_Z}$ (not shown). These large opposite terms close to the surface can logically be explained by use of an idealized Ekman spiral, in a way similar to what has been done for $\overline{k_E}$ in terms of a balance between the zonal component of dissipation and the energetic impact of ageostrophic circulations in zonal average.

4.9 Local results for $\overline{a_Z}$ (diabatic simulation).

Figure 10 (a) shows the zonal available enthalpy component $\overline{a_Z}$ where initial values at day 2 are large in the troposphere (more than 80 J kg^{-1}), with maximum values greater than 100 J kg^{-1} below the jet (from 350 to 600 hPa) corresponding to strong north/south gradients of T^λ and to large values for T^λ_ϕ in Fig. 1 (a).

The total change in $\overline{a_Z}$ is depicted in Fig. 10 (b), including the boundary fluxes of a_Z and a_{cZ} (they cannot be neglected in the boundary layer, not shown). The total change in Fig. 10 (b) is negative in the growing stage of the unstable mode from days 3.5 to 8.5, with a maximum depletion at day 6 in the lower troposphere (from 600 to 800 hPa). The total change is zero at the top of the boundary layer (920 hPa). There is a positive event at 1000 hPa between days 4.5 and 7.5 (more clearly shown with a zoom over this region, not shown here). It is created by a positive part of the generation $\overline{g_Z}$ in Fig. 10 (f) where values up to $25 \cdot 10^{-5} \text{ W kg}^{-1}$ are observed from days 5 to 9.5 and between 1000 and 950 hPa.

Associated with negative tendencies in Fig. 10 (b) are minimum values for $\overline{a_Z}$ in Fig. 10 (a)

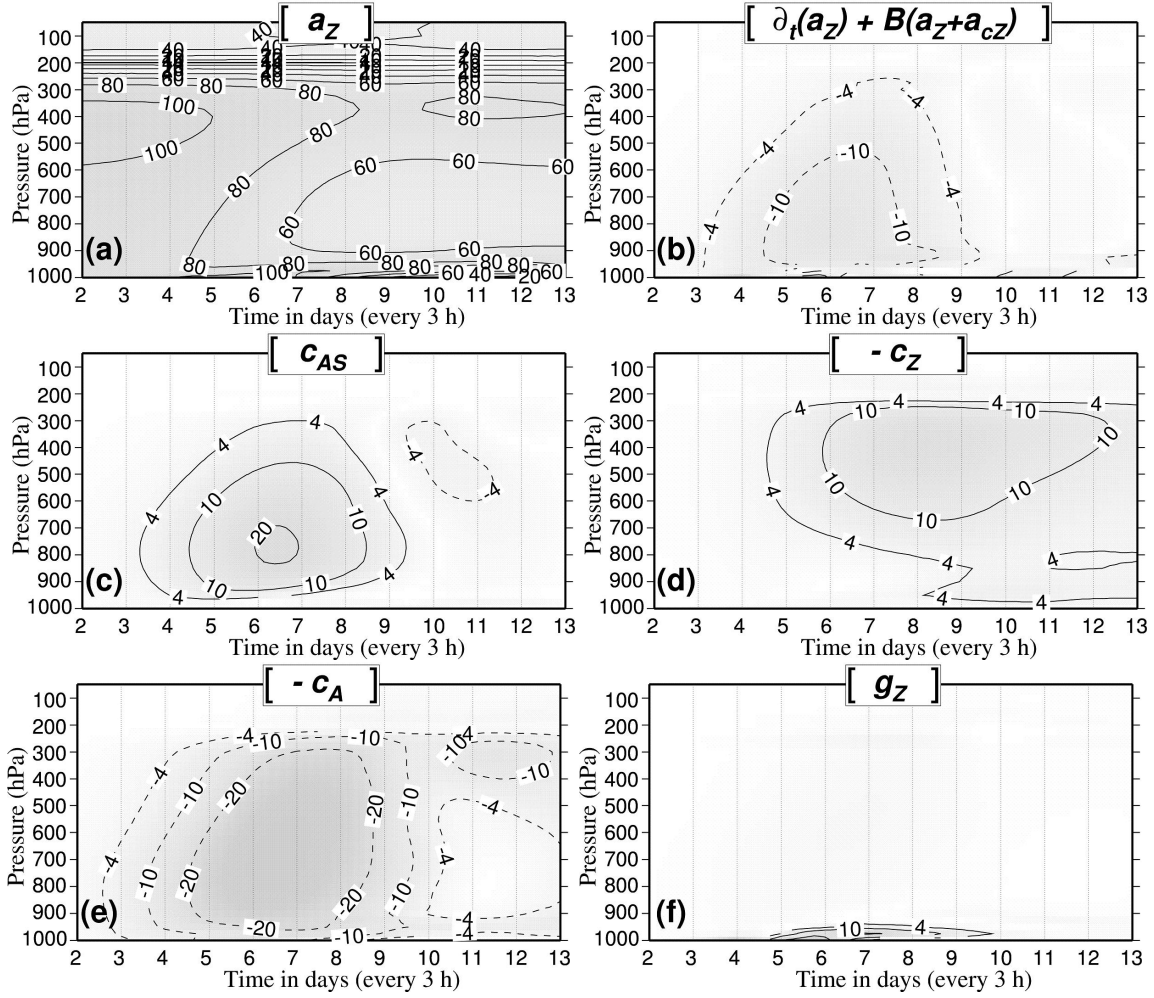

Figure 10: As Fig. 9, with the same large computational domain, with the same units and still for the diabatic simulation EXP-HV, but for the zonal available enthalpy component $\overline{a_z}$. The annotated isopleths are ± 4 , ± 10 , ± 20 , ± 40 , ± 60 , ± 80 and ± 100 . (a) The component $\overline{a_z}$. (b) The total budget of $\overline{a_z}$ writes $\partial_t(a_z) + B(a_z) + B(a_{cz})$: it is the sum of the local time derivative plus the divergence of boundary fluxes. It is equal to (c) + (d) + (e) + (f). (c) The conversion $\overline{c_{AS}}$. (d) The conversion $-\overline{c_Z}$. (e) The conversion $-\overline{c_A}$. (f) The generation $\overline{g_z}$.

after day 8, with values less than 70 J kg^{-1} from 500 to 900 hPa. The behaviour of $\overline{a_z}$ close to the surface is more complex. Values are as low as 20 J kg^{-1} at 1000 hPa and after day 8, with a region of moderate values (more than 70 J kg^{-1}) observed just at the top of the boundary layer (between 975 and 875 hPa, best shown with a zoom over this region, not shown here).

It is explained in section 4.2 how global increases in K_E and K_Z are obtained at the expense of global components A_Z or A_S . However, there is no one-to-one local connection between $\overline{a_z}$ or a_S with $\overline{k_E}$ or $\overline{k_Z}$. The patterns are clearly out of phase because maxima are located at the surface and near the jet for kinematic components, whereas maxima occur in the middle troposphere for the temperature components.

The decrease in $\overline{a_z}$ can be explained by the balance between the positive conversion $\overline{c_{AS}}$ and the negative convection $-\overline{c_A}$ in Figs. 10 (c) and (e). The positive conversion $-\overline{c_Z}$ exports energy from $\overline{k_Z}$ to $\overline{a_z}$ but it does not correspond to change in $\overline{a_z}$. In fact, it is connected to associated negative values for $-\overline{c_A}$. For the jet and the middle troposphere, $-\overline{c_Z}$ and $-\overline{c_A}$ act as direct transfers of energy from $\overline{k_Z}$ to $\overline{a_E}$.

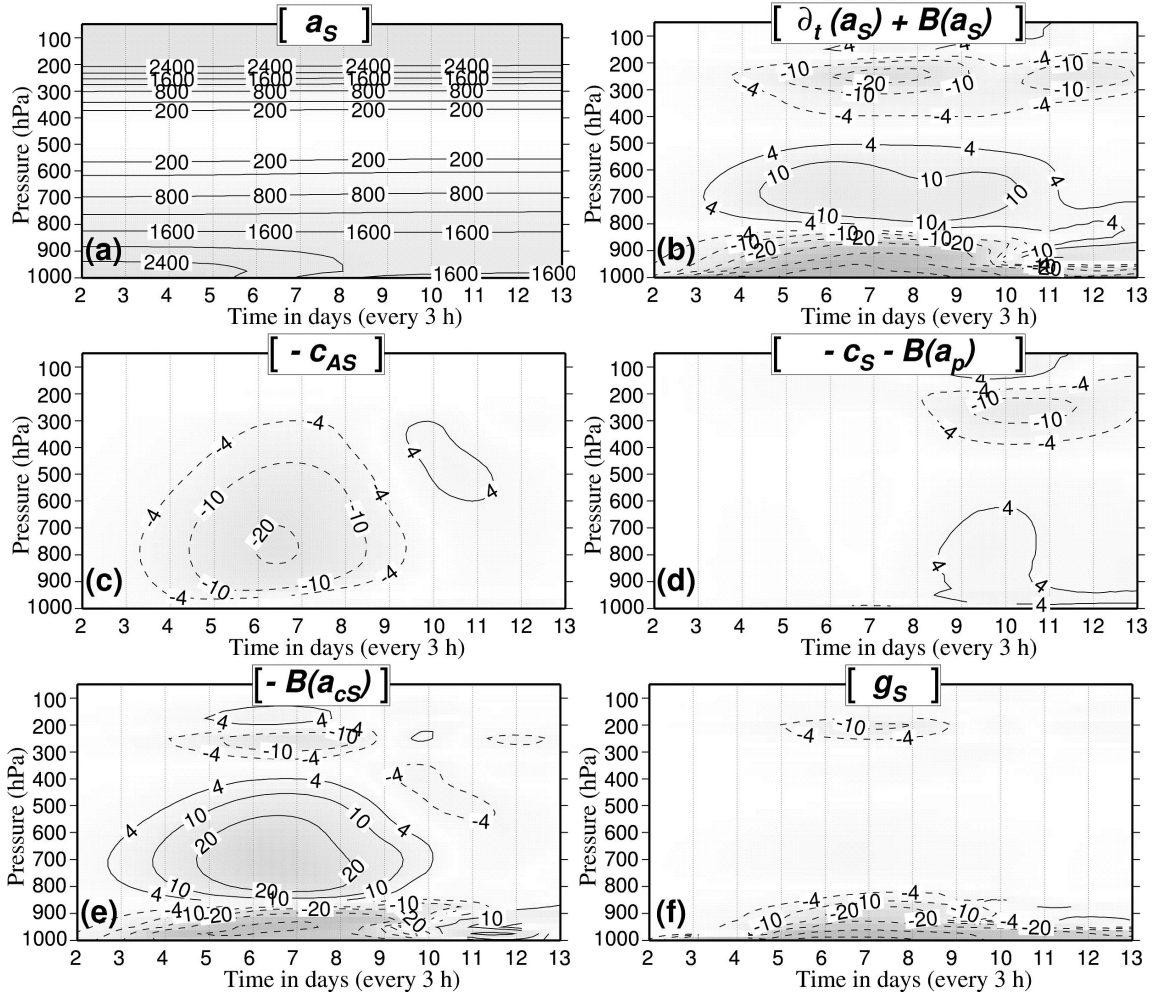

Figure 11: As Fig. 9, with the same large computational domain, with the same interval and units in (b) to (f) and still for the diabatic simulation EXP-HV, but for the static stability component $\overline{a_S}$. Isopleths in (a) are 200, 400, 800, 1200, 1600, 2000 and 2400 J kg^{-1} . For the other panels the annotated isopleths are ± 4 , ± 10 and ± 20 , followed by the contoured isopleths ± 40 , ± 100 and ± 200 $10^{-5} \text{ W kg}^{-1}$. The budget of $\overline{a_S}$ corresponds to (b) = (c) + (d) + (e) + (f). (a) The component a_S . (b) The total budget $\partial_t(a_S) + B(a_S) + \overline{B(a_{cS})}$: it is the sum of the local time derivative plus the divergence of boundary fluxes (c) The conversion $-\overline{c_{AS}}$. (d) The external path budget $-\overline{c_S} - \overline{B(a_p)}$. (e) The boundary term $-\overline{B(a_{cS})}$. (f) The generation $+\overline{g_S}$. The numerous isopleths located near the surface in (b), (e) and (f) are not artefacts. They correspond to real large positive or negative values discussed in the text.

4.10 Local results for $\overline{a_S} = a_S$ (diabatic simulation).

The static stability component a_S in Fig. 11 (a) is maximum in the lower troposphere and in the stratosphere, with minimum values near the 500 hPa level. These observations are in agreement with local values of $(\overline{T} - T_r)^2 \propto a_S$ and with $T_r \equiv 250$ K.

The equation for a_S is equivalent in Fig. 11 to (b) = (c) + (d) + (e) + (f). The development of the mode is mainly associated in Fig. 11 (a) with a decrease of a_S below the level 800 hPa. It corresponds in Fig. 11 (b) to large negative values for the total change in a_S , including the boundary fluxes. Associated with them, large negative values for the generation $\overline{g_S}$ in Fig. 11 (f) are the main cause for the loss of energy in the system, with observed decreasing gradients of temperature below the 800 hPa level.

Clearly, possible one to one local conversions between a_S and $\overline{k_E}$ or $\overline{k_Z}$, suggested in section 4.2 from global results, cannot be established.

Values for the budget $-\overline{c_S} - \overline{B(a_p)}$ are small in Fig. 11 (d). It is a confirmation that the

external path does not contribute greatly to the energetics of the available-enthalpy cycle. As mentioned in the previous section, the conversion $-\overline{c_{aS}}$ in Fig. 11 (c) can explain the growth in $\overline{a_Z}$, although it cannot describe the pattern of the total change in Fig. 11 (a). It means that the other boundary flux $-\overline{B(a_{cS})}$ is an important feature for a_S , acting as vertical redistributions of energy with large positive and negative values but with small global integral (not shown).

5 A new $A3 + K3 + \phi$ available enthalpy cycle.

Investigations of the energetics of the diabatic simulation have shown that observed large and positive values for dissipation in the boundary layer correspond to large and opposite values for the three potential energy conversion terms $-\overline{B(\phi)_S}$, $-\overline{B(\phi)_Z}$ and $-\overline{B(\phi)_E}$. An attempt will be presented in this section to modify (36) and Fig. 5 (b) of Part I in order to take into account these balanced terms which are interpreted, according to OS95 and section 4.6, as vertical redistributions of energy via work done by pressure forces and by ageostrophic circulations.

Ageostrophic conversions are denoted by $\overline{(c_{ag})_X}$, for subscripts $X = (S, Z, E)$. They are written

$$\overline{(c_{ag})_S} = \overline{c_S} - \overline{B(\phi)_S} = -\overline{\mathbf{U}_h \cdot \nabla_p \phi} = \mathbf{k} \cdot \overline{(f \mathbf{U}_g) \times (\mathbf{U}_a)}, \quad (8)$$

$$\overline{(c_{ag})_Z} = \overline{c_Z} - \overline{B(\phi)_Z} = -\overline{(\mathbf{U}_h)_\varphi^\lambda \cdot (\nabla_p \phi)_\varphi^\lambda} = \mathbf{k} \cdot \overline{(f \mathbf{U}_g)_\varphi^\lambda \times (\mathbf{U}_a)_\varphi^\lambda}, \quad (9)$$

$$\overline{(c_{ag})_E} = \overline{c_E} - \overline{B(\phi)_E} = -\overline{(\mathbf{U}_h)_\lambda \cdot (\nabla_p \phi)_\lambda} = \mathbf{k} \cdot \overline{f (\mathbf{U}_g)_\lambda \times (\mathbf{U}_a)_\lambda}. \quad (10)$$

The results obtained in sections 4.3, 4.4 and 4.8 show that local changes in kinetic-energy components are out of phase with baroclinic conversions, whereas they are in one-to-one relationships with ageostrophic conversions. It is thus necessary to reorganize (36) and Fig. 5 (b) of Part I so that the barotropic conversions $\overline{c_E}$, $\overline{c_Z}$ and $\overline{c_S}$ do not directly supply energy to $\overline{k_E}$, $\overline{k_Z}$ and $\overline{k_S}$. Discussions presented in Johnson and Downey (1982) are suitable to solve this problem. They suggest maintaining an explicit degree of freedom for boundary work and to avoid concept of direct conversion between mechanical and thermodynamic energies. This program will be partly retained, leading to modifications in the Lorenz internal cycle (encompassing a hatched area in Fig. 5 (b) of Part I).

The proposal for the new limited-area available-enthalpy cycle is represented by (11) and Fig. 12.

$$\left. \begin{aligned} \overline{\partial_t(a_S)} &= -\overline{B(a_S + a_{cS})} - \overline{c_{AS}} - \{\overline{c_S} + \overline{B(a_p)}\} && + \overline{g_S} \\ \overline{\partial_t(a_Z)} &= -\overline{B(a_Z + a_{cZ})} + \overline{c_{AS}} - \overline{c_Z} - \overline{c_A} && + \overline{g_Z} \\ \overline{\partial_t(a_E)} &= -\overline{B(a_E)} - \overline{c_E} + \overline{c_A} && + \overline{g_E} \\ \overline{B(\phi)} + \overline{B(a_p)} &= +\{\overline{c_S} + \overline{B(a_p)}\} + \overline{c_Z} + \overline{c_E} - \{\overline{(c_{ag})_S} + \overline{(c_{ag})_Z} + \overline{(c_{ag})_E}\} && \\ \overline{\partial_t(k_S)} &= -\overline{B(k_S + k_{cS})} - \overline{c_{KS}} + \overline{(c_{ag})_S} && - \overline{d_S} \\ \overline{\partial_t(k_Z)} &= -\overline{B(k_Z + k_{cZ})} + \overline{c_{KS}} + \overline{(c_{ag})_Z} - \overline{c_K} && - \overline{d_Z} \\ \overline{\partial_t(k_E)} &= -\overline{B(k_E)} + \overline{(c_{ag})_E} + \overline{c_K} && - \overline{d_E} \end{aligned} \right\}. \quad (11)$$

Ageostrophic conversions $\overline{(c_{ag})_X}$ for subscripts $X = (S, Z, E)$ appear in the three kinetic-energy equations in (11). They also appear in the equation for $\overline{B(\phi)}$ which is partitioned into the three incoming terms $\overline{c_X}$ and the three outgoing terms $\overline{(c_{ag})_X}$, plus the term $\overline{B(a_p)}$ added to the two sides of the equation. These transformations between baroclinic and ageostrophic components are equivalent to the vertical redistribution of energy described in OS95.

However, the question as to how values $\overline{c_X}$ are transformed into values $\overline{(c_{ag})_X}$ will not be tackled in this paper, owing to a lack of possible separation of $\overline{\phi}$ into zonal, eddy and static-stability

Figure 12: A new proposal for the limited-area enthalpy cycle. Conversion terms with potential energy $-\overline{B(\phi)}_S$, $-\overline{B(\phi)}_Z$ and $-\overline{B(\phi)}_E$ in Fig. 5 (b) of Part I are combined with $\overline{c_S}$, $\overline{c_Z}$ and $\overline{c_E}$ to form ageostrophic conversions (8) to (10). The potential-energy equation is inserted between available-enthalpy and kinetic-energy components. It is depicted by vertical heavy dotted lines and dark points and the associated non-partitioned generation term is $\overline{B(\phi)} + \overline{B(a_p)}$. The six non-labelled outgoing white arrows represent the boundary fluxes for each of the six energy components. The formulations are given in the first terms on the right-hand sides of (11).

components. Indeed, $\overline{\phi}$ is not a quadratic function and the local separation $\phi = \overline{\phi} + \phi_\phi^\lambda + \phi_\lambda$ disappears for averaged values, because $\overline{\phi_\phi^\lambda} = 0$ and $\overline{\phi_\lambda} = 0$. In fact, this question is equivalent to the other difficulty in understanding the real physical meanings for $-\overline{B(\phi)}_X$ in Eqs.(36) of Part I.

Graphically, Fig. 12 is obtained from Fig. 5 (b) of Part I by folding back $\overline{B(\phi)}_X$ arrows to $\overline{c_X}$ arrows on the right part of the inner Lorenz cycle. The left part of the Lorenz cycle is unchanged and still involves the usual baroclinic conversions. The vertical separation between the two parts corresponds to the equation for ϕ , depicted by vertical heavy dotted lines and dark branching points. The external path of energy is also modified. The boundary term $\overline{B(a_p)}$ is added to $\overline{c_S}$ in order to avoid large terms in the budget of $\overline{a_S}$.

As suggested by Johnson and Downey (1982), connections between potential-energy components and others components do not occur through direct conversions toward kinetic-energy components. Energy coming from ϕ rather enters in the middle of horizontal branches of the internal Lorenz cycle in Fig. 12 (dark points). Transformations leading to (11) are obtained without loss of generality and a gain in simplicity is observed, since there are fewer terms to manage in the kinematic part.

6 An application to the IOP15 of FASTEX.

6.1 Time-Pressure diagrams for IOP15.

It is not the aim of this section to show a complete study of the energetics of IOP15 during the FASTEX experiment (Joly *et al.*, 1997). Only preliminary results will be presented, in order to assess the realistic aspect of the idealized diabatic simulation EXP-HV. Both FASTEX and EXP-HV cases will be investigated with the local available-enthalpy diagnostic package, though with a different limited-area domain.

Figure 13: Time–Pressure diagrams for the IOP15 of FASTEX (13–16 February 1997). Data are available every 6 h and results have been omitted for 1300 and 1600 UTC, because only centred schemes are considered and both initial and final dates cannot be computed. All diagrams can be compared with Figs. 4, 5 and 6. for the other diagrams (b) to (h). The annotated isopleths are ± 20 , ± 40 , ± 100 , ± 200 , ± 400 , ± 800 , ± 1000 and ± 1500 . The equation for k_E corresponds to (b) = (c) + (e) + (f) + (d) or equivalently to (b) = (e) + (g). Units are $J kg^{-1}$ for (a) The component k_E . Units are $10^{-5} W kg^{-1}$ for (b)–(g). (b) The total budget $\partial_t(k_E) + B(k_E)$ (c) The baroclinic conversion \bar{c}_E . (d) The dissipation term $-d_E$. (e) The barotropic conversion \bar{c}_K . (f) The conversion term $-B(\Phi)_E$. (g) The non-barotropic term $-B(\Phi)_E - d_E + \bar{c}_E$. (h) The boundary term $-B(k_E)$.

A three-day forecast has been simulated with an old operational version of the French Arpege model (triangular truncation T149, stretching factor of 3.5, 27 hybrid vertical levels). The operational suite of analyses had used some non-conventional observations and the quality of the forecast was good. The modified time scheme (4) has been used with moving limited-area diagnostic domains following the storm along its trajectory. This method is close to the quasi-Lagrangian method described in Michaelides *et al.*, 1999. However, in this paper, the scheme (4) is evaluated at a given diagnostic time t_0 with the same limited-area for $t_{(-)}$, t_0 and $t_{(+)}$. And when passing from t_0 to $t_0 + \Delta t$, the size and location of the common diagnostic domains change at the same time for the new $t_{(-)} + \Delta t$, $t_0 + \Delta t$ and $t_{(+)} + \Delta t$ diagnostic times in the scheme (4).

Comparisons of diagrams between Figs. (13) (a) and (5) (a) show that the idealized diabatic experiment EXP-HV can reproduce some of energetic features observed in IOP15 of FASTEX. In the two cases, the eddy component $\overline{k_E}$ is a maximum close to the jet and in the boundary layer at a level above the surface. The main differences concern the values of $\overline{k_E}$ which are enlarged, going from 30-50 units for EXP-HV to 200-300 units for FASTEX. Another difference is that the maximum close to the surface occurs 12 h later than for the jet in the FASTEX experiment. The contrary is observed in EXP-HV.

Patterns of total budget in Figs. (13) (b) and close to the surface are similar, with a maximum of development of $\overline{k_E}$ on 14–12 h and at level 950 hPa for FASTEX. However, total budgets close to the jet are very different. The explanation is given by Fig. (13) (h) where the boundary flux is equivalent and opposite to the local tendency, leading to weak values of the sum $\partial_t(k_E) + B(k_E)$ depicted on Fig. (13) (b). As a consequence, advection processes seem to control energetics of the jet in FASTEX, whereas local developments appear to be the prevailing sources of $\overline{k_E}$ in the boundary layer. Such advection processes for the jet could not appear in EXP-HV because of the eight waves surround the earth. Even for a small limited area, the incoming and outgoing energy is equal for EXP-HV.

Patterns for the baroclinic and barotropic conversions, the dissipation term and the conversion term with potential energy are to a large extent similar for idealized EXP-HV and for the real FASTEX experiments (see the Figs. (13) (c)–(f)). In particular, the dissipation is generally weak above the boundary layer, though with surprising negative large values close to 400 hPa and centred on day 14 at 12 h.

The non-barotropic term in Fig. (13) (g) can be compared with 6 (b). As for the total budget in Fig. (13) (b), there are large differences for the jet region of FASTEX, where increase in $\overline{k_E}$ is mainly due to advection processes. For FASTEX as for EXP-HV, the ageostrophic conversion, equivalent to (g)–(d) in Fig. (13), seems to be the relevant term (not shown) to explain the forcing coming from $\overline{a_E}$, in place of the usual baroclinic conversion $\overline{c_E}$.

6.2 The available-enthalpy cycles for IOP15.

The available-enthalpy cycles presented in Fig. 14 correspond to the storm investigated during the IOP15 of FASTEX and already described in the previous section (see Fig. 13). The cycles are computed for three vertical layers (upper, middle and lower troposphere) and for the two growing and decaying stages of development of the storm. The vertical integral of any term X is equal to the sum of $X dp/g$, where g is the acceleration due to gravity. Units are W m^{-2} . The contributions to the global budget of upper, middle and lower pressure layers are equal to 35, 45 and 15%, respectively, according to the differences in pressure for the layers.

The main objective of this section is to determine how far the ageostrophic conversions $\overline{(c_{ag})_X}$ acting on $\overline{k_X}$ can differ from the baroclinic conversions $\overline{c_X}$ acting on $\overline{a_X}$, for the subscripts $X = (S, Z, E)$. Clearly, Figs. 14 (a)–(e) show that the differences between the two kinds of conversion terms can be large, for all layers and for the two stages of the storm.

An important example is the low-level growing stage cycle shows in Fig. 14 (e). It corresponds

Figure 14: The available-enthalpy cycles for the IOP15 of FASTEX. The boxes, circles and arrows correspond to the cycle (11) and to Fig. 12. Left column: the first growing stage from the 18 UTC 13 February to the 06 UTC 14 February. Right column: the last mature and decaying stages from 18 UTC 14 February to the 06 UTC 15 February. Units are $W m^{-2}$. (a) and (b) Upper-troposphere and stratosphere region (50 to 400 hPa). (c) and (d) Middle-troposphere region (400 to 850 hPa). (e) and (f) Lower-troposphere and boundary-layer region (850 to 1000 hPa).

to an ageostrophic conversion of +5.7 units and to a baroclinic conversion of only +1.8 units. The difference of -3.9 units for $(\overline{a_E}, \overline{k_E})$ represents the eddy contribution for $\overline{B(\phi)} + \overline{B(a_p)}$, with the contributions of -0.4 units for $(\overline{a_Z}, \overline{k_Z})$ and +4.3 units for $(\overline{a_S}, \overline{k_S})$, leading to the observed small total change of +0.1 units.

This low-level growing-stage cycle corresponds to typical features of baroclinic developments for midlatitude storms. The generation term $\overline{g_S} = +6.7$ and the conversion term $\overline{c_S} = +5.1$ are associated with a release of $\overline{a_S}$ reaching -3.3 units, with the sequence of positive conversion terms $\overline{c_{AS}} = +2.1$, $\overline{c_A} = +3.7$, $\overline{c_E} = +1.8$ and $(\overline{c_{ag}})_E = +5.7$ units. The budget of $\overline{k_E}$ is closed by a barotropic instability $\overline{c_K} = +0.4$, with a growing of +2.7 units for $\overline{k_E}$ and a realistic dissipation term $\overline{d_E} = 3.2$ units.

The main difference between the low-level growing stage in Fig. 14 (e) and the mature or decaying stage in Fig. 14 (f) is the expected change of sign for the barotropic conversion ($\overline{c_K} = -1.0$). This barotropic stabilization corresponds to a growth of $\overline{k_Z}$ (+0.5 units). The dissipation terms increase for the mature stage, reaching 1.6 units for $\overline{d_Z}$ and 8.8 units for $\overline{d_E}$. The large values for the eddy dissipation balance the large ageostrophic conversion (+12.2 units), giving an explanation to the observed moderate growth of $\overline{k_E}$ (only +1.2 units).

The total budget for $\overline{B(\phi)} + \overline{B(a_p)}$ is small (+0.1 units) only for the low-level growing stage in Fig. 14 (e). Larger values from -38.8 to $+8.7$ units are observed for all other cases (Figs. 14 (a) to (d), and (f)). It means that the budget of potential energy plays an important role in the available-enthalpy cycle by supplying (extracting) energy to (from) other forms of energy. There is a need to elucidate the uncertain involved processes.

The conversion terms $\overline{c_Z}$ and $\overline{(c_{ag})_Z}$ have opposite signs for the three decaying stage cases (Figs. 14 (b), (d) and (f)), whereas they have the same signs for the three growing-stage cases (Figs. 14 (a), (c) and (e)). Other comparisons between the eddy ageostrophic and baroclinic conversions show that $\overline{(c_{ag})_E}$ is the governing term for the upper-level and for the lower-level cases (Figs. 14 (a), (b), (e) and (f)). The governing term is $\overline{c_E}$ for the mid-troposphere cases (Figs. 14 (c) and (d)).

These comparisons can be understood by analysing the vertical and time distributions for $\overline{c_E}$ and $-\overline{B(\phi)_E}$, as depicted in Fig. 13 (c) and (f), respectively. According to (10), the ageostrophic conversion is the sum of the two terms: $\overline{c_E} - \overline{B(\phi)_E} = \overline{(c_{ag})_E}$. For the mid-tropospheric region they have opposite sign, leading to the observed small values of $\overline{(c_{ag})_E}$. For the low-level troposphere, the two terms are positive, leading to the large positive values for $\overline{(c_{ag})_E}$. For the upper-levels region the sign of $-\overline{B(\phi)_E}$ is somewhat irregular close to the jet. The observed increase of $\overline{(c_{ag})_E}$ is less easy to explain.

7 Conclusions.

The aim of this paper was to investigate the local energetics of idealized simulations of adiabatic and diabatic versions of baroclinic waves. The final diagnostic tool is the fully symmetric limited area available enthalpy cycle with $A3 + K3 + \phi$ components, defined by (11) and Fig. 12.

As stated in McIntyre (1980) and Plumb (1983), the transformed Eulerian-mean systems or the generalized Eliassen-Palm fluxes can lead to better ways of analysing wave and mean-flow interactions.

Furthermore, the partition of Lorenz into *zonal mean* and *eddy* components of the flow could be improved in many ways, for instance by following variational processes as suggested by Van Mieghem (1956), Plumb (1983) and Kucharski (1997). An example of the use of a flow-dependent reference state is given in Kucharski and Thorpe (2000a), where *rotated zonal means* are defined. But in this two-part paper, the conventional partition of Lorenz has been considered and the same choice has been made in the most recent papers of Michaelides et al. (1999), Kucharski and Thorpe (2000b, 2001) or Mishra and Rao (2001).

As for the non-uniqueness of energy cycles widely discussed in Johnson and Downey (1982) and in Plumb (1983), the definition of the limited-area available enthalpy cycle (11) suffers from the same general problem of uncertainty in the interpretations of conversion terms. It is, for instance, always possible from a mathematical point of view to cancel out any branch of a cycle, by adding a common term to each part of a closed loop. The simplest example is a triad of energy components (e_1, e_2, e_3) with the conversions $C_{(1,2)}$, $C_{(2,3)}$ and $C_{(3,1)}$ acting between them. If the quantity $-C_{(3,1)}$ is added to the three branches, the modified cycle is still valid and both the energy and net tendencies are the same before and after the modification. The impact on the diagram for the triad-cycle would be of a cancellation of the direct conversion between e_1 and e_3 , the other conversions becoming $C_{(1,2)} - C_{(3,1)}$ and $C_{(2,3)} - C_{(3,1)}$.

It is thus important to verify that the physical interpretations of the modified conversion and flux terms are still valid in the available-enthalpy cycle (11), as stated in McIntyre (1980), Johnson and Downey (1982), and Plumb (1983).

Firstly, it has been verified that there are no approximations and no missing terms, by showing

that observed dissipation and generation residuals are small in case of adiabatic simulations in both global and local cases. Furthermore, there is a real gain in physical basis in the definition of the new available enthalpy cycle. In (11) and Fig. 12, Lorenz's internal cycle has been modified in order to highlight the ageostrophic conversion $-\mathbf{U}_h \cdot \nabla_p(\phi)$. It acts as a forcing directly applied to the kinetic-energy components, in place of the usual baroclinic conversion $-R \omega T/p$.

The potential-energy component plays the role of vertical redistribution of energy as described in OS95, by transforming baroclinic into ageostrophic conversions, via unknown processes to be discovered. The use of ageostrophic conversion terms in the available-enthalpy cycle is the main modification brought to the study of Pearce (1978). It appears to be in agreement with the results obtained with the numerical simulation of the IOP15 of FASTEX, as presented in section 6.2. The magnitudes of the baroclinic and ageostrophic conversions are indeed very different. Even their sign can change. When the potential-energy component is included, the values of the generation and dissipation terms computed as residuals of the cycle (11) turn out to be realistic.

Other comparisons of results from the idealized case EXP-HV and from the IOP15 real case of FASTEX show that surface patterns are almost the same, although the jet energetics are very different. It could be worthwhile to continue this study on IOP15 of FASTEX, with special attention paid to the impact of surface energy fluxes on the atmospheric boundary-layer front, as already stated in Giordani and Planton (2000).

The limited area available enthalpy cycle (11) must be particularly suitable for studying the energetics of isolated structures like frontal waves, for which FASTEX has been organized. To do so, the potential-vorticity inversion mechanism could be used to make simulations including and not including some localized small patterns, in order to understand their dynamical consequences.

Other idealized cases could be investigated in the future, with possible enhanced horizontal or vertical resolutions. It could also be worthwhile to define more realistic simulations, by including humidity and other diabatic processes. Results from Marquet (1993) could serve as a starting point for defining a moist local available-enthalpy cycle.

Acknowledgements.

The author is most grateful to S. Malardel, Ph. Arbogast and C. Freydier for their support and useful discussions about applications of available-enthalpy energetics to idealized simulations and for the preparation of the basic state with the most unstable mode. I also thank R. Clark and the two referees who suggested many clarifications and modifications to the manuscript.

Appendix A. Computations of the pseudo-geostrophic wind.

The stationary jet depicted in Fig. 1 (a) is defined by the pseudo-geostrophic wind ($u_g^*, v_g^* = 0$). It is obtained from (29) of Part I, together with the hypotheses that all the zonal and meridian tendencies are zero and that all the variables (T, ϕ, u_g^*) are zonally symmetric, with a constant surface pressure and without friction. The result is given by (A.1) .

$$\frac{dv_g^*}{dt} = -[\nabla_p(\phi)]_y - f^* u_g^* = 0. \quad (\text{A.1})$$

If the usual geostrophic wind is denoted by $u_g = -[\nabla_p(\phi)]_y/f$, the pseudo-geostrophic version is obtained by solving an equation of the second degree, derived by inserting $f^* = f + u_g^* \tan(\varphi)/\mathcal{R}$, into (A.1), to give

$$(u_g^*)^2 \frac{\tan(\varphi)}{\mathcal{R}} + f u_g^* + [\nabla_p(\phi)]_y = 0 \implies u_g^* = \mathcal{V}_T \left\{ \sqrt{1 + 2u_g/\mathcal{V}_T} - 1 \right\}. \quad (\text{A.2})$$

The term $\mathcal{V}_T = \Omega \mathcal{R} \cos(\varphi)$ is the velocity due to the rotation of the earth with $\Omega \mathcal{R} \approx 464 \text{ m s}^{-1}$. The limit of (A.2) for small values of u_g/\mathcal{V}_T and with $\sqrt{1 + 2X} - 1 \approx X$ for small X is the usual

geostrophic wind u_g . This approximation is valid in the tropical region where $\cos(\varphi) \approx 1$ and $u_g \ll 464 \text{ m s}^{-1}$. But \mathcal{V}_T decreases with increasing latitude where $\cos(\varphi) \approx 0$, leading to possible large differences between u_g^* and u_g . A significant departure from classic geostrophic conditions (up to 4 m s^{-1}) is also obtained for the mid-latitude jet. The obvious singularities for $\varphi = 0$ and $\varphi = \pm\pi/2$ in (A.2) have no practical impact for a Gaussian grid where there is no point located at the poles or at the exact equator.

There is a need to take into account the formulation (A.2) to avoid significant time oscillations of the jet due to imbalanced wind, as clearly observed for some spectral coefficients in a first attempt to construct the zonal jet. The method of computing “ $[\nabla_p(\phi)]_y$ ” is also important. The method used in Arpege is a spectral computation of the gradient of temperature for “ $\cos(\varphi)\partial_\varphi(T)$ ”, with a transformation onto the Gaussian grid. The meridian component “ $(\mathcal{R})^{-1}\partial_\varphi(\phi)$ ” is finally obtained by computing the vertical integral of the hydrostatic equation and by a division by “ $\mathcal{R}\cos(\varphi)$ ” on the Gaussian grid.
